Resources: [\[\[KBxSNPPCR\]\]](#) Instructions

1.0.1 | Part One

Outline

- basics
- function and regulation
- SNP effect

Writing!

The *COMT* gene, or catechol-O-methyltransferase, encodes the *COMT* enzyme which is responsible for breaking down neurotransmitters in the brain's prefrontal cortex. More specifically, it acts as a catalyst for the transfer of a methyl group from S-adenosylmethionine to dopamine, epinephrine, and norepinephrine. This process, called O-methylation, leads to the degradation of the aforementioned neurotransmitters. The *COMT* enzyme also affects the metabolism of exogenous substances, but that is irrelevant for the mutation at hand. The *COMT* gene itself is 27.22kb long and located on chromosome 22q11.2. It has ubiquitous expression in 27 tissues, including the placenta, the adrenal, and the lung. Val158Met, also known as rs4680, is a common missense mutation swapping a valine for a methionine.
