## 2 | **overview**

### 2.1 | **mitosis gene transmission**

#### 2.1.1 | **exact copy (except random mutations)**

#### 2.1.2 | **good for growth and expansion as a child or to replace damaged tissue**

#### 2.1.3 | **things can still differ**

1. random mutations
2. chromosome duplication ('polytene chromosomes')
  - (a) large compared to other chromosomes
  - (b) created in a similar process to mitosis but without 'cytokinesis'

### 2.2 | **meiosis**

#### 2.2.1 | **only transmits half the genetic information**

#### 2.2.2 | **fundamental to all plants and animals producing gametes**

#### 2.2.3 | **independent assortment**

1. ordering is random, which means each half-chromosome has a 1/2 chance of continuing on
2. thus, each organism can produce  $2^n$  gametes
3. and when considering both parents the number of possible child genomes is squared? (ignoring recombination)

### **3 | recombination**

3.1 | **some mixing of chromosome pieces 'between homologue pairs'?**

3.2 | **more common in some genes than others (if they are tightly linked)**

### **4 | when things go wrong**

4.1 | **aberrations that alter chromosome number**

4.1.1 | **occurs when something happens to the 'centromere' and the 'spindle fibers' can't attach to it and pull it apart**

4.1.2 | **one daughter cell can end up with more chromosomes than another in mitosis**

4.1.3 | **in meiosis, 'homologous pairs can fail to separate during anaphase I'. called 'nondisjunction'**

4.1.4 | **diff numbers of chromosomes for haploid (half-set sex cells)**

1. monosomy

(a) lacking one chromosome (organism has only half chromosome from other parent)

2. trisomy

(a) got three half-chromosomes, (organism has extra bit, such as XXY)

3. aneuploidy (either of the above)

## 5 | **an example : albert francis blakeslee, john bellings, and jimsonweed**

## 6 | **summary**

6.1 | **odd chromosome number arises from errors in segregation during chromosome replication. These variations 'enrich our understanding of how the transfer of chromosomes is regulated from one generation to the next'**

## 7 | **meiosis**

### 7.1 | **etymology**

7.1.1 | **from greek *meioun* or 'to make small'**

7.2 | **one dna replication stage, two cell divisions**

7.3 | **also involves 'recombination'**

7.4 | **often study yeast or something**

7.5 | **better (electron scanning) microscopes made more discoveries**

7.6 | **differences by sex**

7.6.1 | **mamalian males tend to mantain an active pool of mitosis dividing germ cells of which a subset "specialize" via meiosis**

7.6.2 | **mamalian females germ cells tend to enter meiosis and become oocytes early in development (limited number)**

7.7 | **steps to meiosis**

7.7.1 | **young organisms set aside germ cells that proliferate by mitosis until they recieve signals and enter meiosis**

7.7.2 | **two divisions to produce gametes**

7.7.3 | **first, as a diploid cell, the genome is duplicated to get four copes distributed over two of each chromosome**

### 1. meiosis I

(a) unique to germ cells

(b) prophase I

i. 'pairs of homologous chromosomes come together to form a tetrad or bivalent, which contains four chromatids'

ii. recombination occurs within each tetrad

iii. chiasmata, or something?

(c) metaphase I

- i. chromosomes line up opposite each other
  - ii. sex chromosomes also oppose each other (to ensure sex chromosomes segregate properly during division (in theory))
- (d) anaphase I
  - i. crossover resolution with meiosis-specific cohesins?
  - ii. else aneuploidy
    - A. which is actually quite common, maybe 10% to 30%
    - B. increases sharply with maternal age
- 2. meiosis II
  - (a) similar to mitotic division
  - (b) except there isn't enough DNA to go around so each daughter cell has only half of each chromosome (haploid, as expected)
  - (c) in males, all four products are roughly the same size and viability while in females, the oocyte retains most of the mass and the other three bits are pinched off

## 7.8 | **recombination (v important)**

### 7.8.1 | **segments:**

1. leptotene (greek 'thin threads')
2. zygotene (greek 'paired threads')
3. pachytene (greek 'thick threads')
4. diplotene (greek 'two threads')

### 7.8.2 | **whappens**

1. some species have pairing sequences for centered alignment
2. other species, chromosomes don't pair until double stranded breaks (DSBs) appear in DNA
  - (a) catalyzed by proteins with topoisomerases, Spo11 protein from yeast?
3. some DNA trimming and then they connect in double Holliday junctions
4. synaptonemal complex (SC) which holds things steady
