1 | Mutation and Inheritance

1.1 | Cell Division, Cell Cycle & It's Regulation

Each cell lives and reproduced on a cycle; unsurprisingly, this is called the [KBhBIO101CellLifecycle](#)!

- These cell cycles create [KBhBIO101GeneticVariation](#), even in [KBhBIO101Mitosis](#), because yes!, in mitosis, there could be [KBhBIO101Mutations](#) which introduce variation
- However [KBhBIO101Mutations](#) could cause cancer if left unchecked, so we have [KBhBIO101CellCycleRegulation](#) to keep this cycle check.

At the end of the cell cycle, a little bit of a thing happens where the cell replicates (or makes off-springs, so not necessarily exact copies of) itself. This bit of a thing's called [KBhBIO101CellReproduction](#).

- This reproduction process uses one of either [KBhBIO101Mitosis](#) (exact copy, for somatic cells (not sperm/egg) only) or
- [KBhBIO101Meiosis](#) (half, randomly-mixed genetic info, for gametes (sperm/egg) only).

1.2 | Genetics and Inheritance

[KBhBIO101GeneticVariation](#) is like, really good. However, its woefully complicated and there are at least 3 ways I think of that it happens.

DNA's sequence could vary by itself, and that will cause a [KBhBIO101Mutations](#), which is actually very rarely bad news bears and instead simply introduces genetic variation if not doing nothing at all.

Organisms have different traits, and through [KBhBIO101Meiosis](#) these traits are mixed. But! which one of these traits are expressed (dad passed blue-eye, mom passed red-eye, which one expressed?)? Well, find out at [KBhBIO101Inheritance](#).

Specifically, the mixture of a "heterozygous" of

- Connecting protein function to expressed traits in organisms
 - Given an individual with two particular alleles of a gene, what trait would you expect to see.
- Connecting protein function and traits to inheritance patterns:
 - Given parents with particular alleles of genes, what would you expect in their offspring and why.
